## ABSTRACT

We study the environmental dependence of stellar population properties at  $z \sim 1.3$ . We derive galaxy properties (stellar masses, ages and star formation histories) for samples of massive, red, passive early-type galaxies in two high-redshift

clusters, RXJ0849+4452 and RXJ0848+4453 (with redshifts of  $z = 1.26$  and  $1.27$ , respectively), and compare them with those measured for the RDCS1252.9-2927 cluster at  $z=1.24$  and with those measured for a similarly mass-selected sample of field contemporaries drawn from the GOODS-South Field. Robust estimates of the aforementioned parameters have been obtained by comparing a large grid of composite stellar population models with extensive 8-10 band photometric coverage, from the rest-frame far-ultraviolet to the infrared. We find no variations of the overall stellar population properties among the different samples of cluster early-type galaxies. However, when comparing cluster versus field stellar population properties we find that, even if the (star formation weighted) ages are similar and depend only on galaxy mass, the ones in the field do employ longer timescales to assemble their final mass. We find that, approximately 1 Gyr after the onset of star formation, the majority (75%) of cluster galaxies have already assembled most ( $> 80\%$ ) of their final mass, while, by the same time, fewer (35%) field ETGs have. Thus we conclude that while galaxy mass regulates the timing of galaxy formation, the environment regulates the timescale of their star formation histories.

*Subject headings:* galaxies: clusters: individual: RXJ0849+4452, RXJ0848+4453, RDCS1252.9-2927 — galaxies: high-redshift — galaxies: fundamental parameters — galaxies: evolution — galaxies: formation — galaxies: elliptical — cosmology: observations

## 1. Introduction

Galaxies reside in environments that span a wide range of density. In order to understand the physical processes that drive their evolution is important to test for systematic differences between galaxies in various environments. Many authors have shown that population density plays an important role in determining many galaxy properties, such as star formation rate, gas content and morphology (Kodama & Bower 2001; Balogh et al. 2002). Several mechanisms have been proposed by theorists to account for these effects, such as ram pressure stripping, mergers and tidal effects (Gunn & Gott 1972; Dressler et al. 1997; Moore et al. 1996, 1998, 1999).

More than half of all stars in the local Universe are found in massive spheroids (e.g., Bell et al. (2003)). The history of mass assembly and star formation of these Early-Type Galaxies (ETGs) are among the most actively pursued elements in galaxy evolution studies, and form the basis for models of massive galaxy formation (Renzini 2006).

Galaxy clusters provide an ideal laboratory to study ETGs, the dominant galaxy population in clusters, even beyond redshift one. In addition, large field surveys have multiplied in recent years, extending the baseline over which environmental effects can be studied.

Studies indicate that the most massive ETGs *in the field* may be amongst the oldest at any given epoch (Cimatti et al. 2004; Fontana et al. 2004; Saracco et al. 2004; Treu et al. 2005; Juneau et al. 2005; di Serego Alighieri et al. 2005; Pannella et al. 2009). They have evolved mainly passively since  $z \sim 1$  and, at least the most massive ones, as slowly as cluster galaxies (van Dokkum & Franx 1996; Bernardi et al. 1998; Treu et al. 1999; Kochanek et al. 2000; van Dokkum & Franx 2001; Treu et al. 2001; van Dokkum & Stanford 2003; De Propris et al. 2007). Similarly, tight constraints have been placed on the scatter and slope of the color-magnitude relation (CMR), the Fundamental Plane (FP) (Jørgensen et al. 2006; Treu et al. 2005; van der Wel et al. 2005; di Serego Alighieri et al. 2006; van Dokkum & van der Marel 2007) and Balmer line strengths (Clemens et al. 2006; Sánchez-Blázquez et al. 2006) of the ETGs populating *massive clusters*, indicating a very high formation redshift for the ETGs in clusters as well (Rettura et al. 2006; Eisenhardt et al. 2008; Rettura et al. 2010; Gobat et al. 2008; Mei et al. 2009; Collins et al. 2009; Rosati et al. 2009).

The most distant clusters known to date provide the strongest leverage on model predictions (Papovich et al. 2010; Tanaka et al. 2010a). Specifically, there is a tight CMR of ETGs at  $0.8 < z < 1.5$  (Blakeslee et al. 2003; Blakeslee et al. 2006; Mei et al. 2006a,b; Lidman et al. 2008; Hilton et al. 2009; Strazzullo et al. 2010), a slowly evolving  $K$ -band luminosity function seemingly at odds with hierarchical merging scenarios (Toft et al. 2004; Strazzullo et al. 2006), and a tight and slowly evolving FP out to  $z \approx 1.2$  (Holden et al. 2005). The existence of such massive, passively evolving galaxies already at  $z \gtrsim 0.8$  needs to be reconciled with the evidence for massive (often dusty) star-forming populations found at  $z \gtrsim 2.2$  both in the field and in overdense environments (Steidel et al. 2005; Adelberger et al. 2005; Kodama et al. 2007; Miley & De Breuck 2008; Overzier et al. 2009; Tanaka et al. 2010b).

Previous studies based on optical and infrared data have placed some constraints on the star formation histories of ETGs in distant clusters based on the scatter in their CMRs: the best-fit models yield formation epochs of  $2 < z_f < 7$  (Blakeslee et al. 2003), but a greater accuracy could not be achieved based on the available rest-frame optical and infrared data alone. The reason for this is that age-dependent features in galaxy spectra (e.g., the 4000 Å break or the 1.6  $\mu m$  bump) are too broad or evolve too slowly to be used as adequate age indicators (Burstein et al. 1988; Tantalo et al. 1996; Maraston 2005; Rettura et al. 2010). In order to better constrain the formation epoch ( $z_f$ ) of ETGs we need to probe the much sharper and fast-evolving rest frame UV-optical colors that will allow us to determine  $z_f$  with

much greater accuracy than hitherto achieved, enabling us to better constrain the entire SFH of ETGs<sup>1</sup> (see also Fig.2 of Rettura et al. (2010))

In order to provide a key test of the paradigm of an accelerated evolution in the highest density environments (Diaferio et al. 2001; Thomas et al. 2005), in this work, on the basis of photometric data available over the rest-frame wavelength range  $0.15 - 2\mu\text{m}$ , we compare stellar masses, ages and inferred star formation histories of ETGs found in three massive X-ray detected clusters at  $z \sim 1.3$  (RXJ0849+4452, RXJ0848+4453, RDCS1252.9-2927) with a sample of field contemporaries drawn from the GOODS South Field.

The structure of this paper is as follows. The description of our datasets, cataloging and sample selection is described in §2. In §3 we describe our methods in inferring star formation histories, ages and masses from stellar population analysis. The results of our study are discussed in §4, while in § 5 we summarize our conclusions.

We assume a  $\Omega_\Lambda = 0.73$ ,  $\Omega_m = 0.27$  and  $H_0 = 71 \text{ km} \cdot \text{s}^{-1} \cdot \text{Mpc}^{-1}$  flat universe (Spergel et al. 2003), and use magnitudes in the AB system throughout this work.

## 2. Description of the data

This work is based on data collection programs on the three galaxy clusters at  $z \sim 1.3$  which are amongst the most extensive spectroscopic and photometric surveys available over the wavelength range  $0.35 - 4.5\mu\text{m}$ . To compare cluster galaxy properties with the field, we also take advantage of similar-quality archival data available for the GOODS-South Field. Tab. 1 summarizes the rich and homogeneous dataset employed in this study.

### 2.1. RX J0849+4452 and RX J0848+4453

The Lynx Supercluster, is the highest redshift supercluster known today (Nakata et al. 2005), with two central X-ray detected galaxy clusters and three spectroscopically confirmed surrounding groups. This work focuses in particular on the cores of the two main clusters, RX J0849+4452 (hereafter, Lynx E) and RX J0848+4453 (hereafter, Lynx W), both detected in the ROSAT Deep Cluster Survey (Rosati et al. 1999) and spectroscopically confirmed at  $z = 1.261$  (Rosati et al. 1999) and  $z = 1.273$  (Stanford et al. 1997), respectively. Furthermore,

---

<sup>1</sup>Note that by  $z \gtrsim 1.3$  not enough cosmic time has elapsed for HB stars to produce the “UV upturn” (Yi et al. 1997, 1999).

in two accompanying papers (Raichoor et al. 2011; Mei et al. 2011) we also compare ETGs stellar population properties in the two cluster cores with those of the ones in the surrounding groups.

Both Lynx E and Lynx W were observed in the  $u'$  filter with the blue channel of LRIS on Keck I in two separate epochs. On March 4th, 2003, exposures totaling 260 min were obtained in conditions that were photometric with  $0.8''$  seeing. A further 240 min was obtained during the night of March 1st, 2008, with clear skies and a typical seeing of  $0.9''$ . The two epochs of data were reduced separately using standard IRAF tasks, where we subtracted the bias level, flat-fielded each exposure using a series of twilight flats obtained on each night, astrometrically calibrated and aligned each image by comparison to star positions from the HST GSC2.2 catalog and then refined with a larger number of stellar positions from the SDSS DR6 catalog. Finally, the images were flux-calibrated, also correcting for atmospheric extinction, using exposures of various photometric standard stars obtained across a range of airmasses each night, and then combined. The two sets of images were taken at different position angles, and so the combined frame has an effective exposure time of 8 hrs 20 min across much of the field, but a shallower depth at the edges of the field where the frames do not overlap. The effective resolution in the combined ultraviolet image is  $0.95''$ .

In order to sample the optical-to-infrared wavelength domain, we have obtained data in the following passbands, R,  $i_{F775W}$ ,  $z_{F850LP}$ , J, Ks, and *Spitzer*/IRAC channels,  $3.6\mu\text{m}$  (ch1) and  $4.5\mu\text{m}$  (ch2).

We refer the reader to the companion paper by (Raichoor et al. 2011) for a more detailed description of the optical and infrared dataset used in this work (see also their Tab.1).

Here we remind that the R-band images were obtained with the Keck/LRIS instrument. The  $i_{F775W}$  and  $z_{F850LP}$ -band were observed in the  $F775W$  and  $F850LP$  filters provided by the ACS-Wide Field Camera (WFC) on board of the Hubble Space Telescope. We note that these two observing filters have been purposely chosen to bracket the  $4000\text{\AA}$ -break of a model elliptical galaxy at  $z = 1.26 - 1.27$  (Mei et al. 2006a,b).

The near-infrared imaging data ( $J, K_s$ -band) were acquired with the FLAMINGOS instrument available at the Kitt Peak National Observatory (KPNO).

Mid-Infrared imaging was obtained (in two channels at  $[3.6\mu\text{m}]$  and  $[4.5\mu\text{m}]$ ) with the IRAC camera on board of the *Spitzer* space telescope.

## 2.2. RDCS1252.9-2927 and the GOODS-South field.

This work builds on datasets and analyses already performed on ETGs belonging to the X-ray luminous cluster, RDCS1252.9-2927 (hereafter, CL1252), and to the GOODS-South field, centered on the so-called Chandra Deep Field South field (hereafter, CDFS), as reported by Rettura et al. (2010); Gobat et al. (2008).

We refer to the aforementioned papers for more details in the data reduction. Here we note that the data we have employed for the CL1252 cluster consist of deep imaging in 10 bands: *VLT/VIMOS* ( $U$ ), *VLT/FORS2* ( $B$ ,  $V$ ,  $R$ ), *HST/ACS* ( $i_{F775W}$ ,  $z_{F850LP}$ ) (Blakeslee et al. 2003), *VLT/ISAAC* ( $J_s$ ,  $K_s$ ) (Lidman et al. 2004), *Spitzer/IRAC* ( $3.6\mu m$ ,  $4.5\mu m$ ), as well as spectroscopic data taken with *VLT/FORS2* and published in Demarco et al. (2007).

The archival data for the comparison field, the CDFS, comprises deep imaging in 9 bands: *VLT/VIMOS* ( $U$ ) (Nonino et al. 2009), *HST/ACS* ( $B_{F435W}$ ,  $V_{F606W}$ ,  $i_{775W}$ ,  $z_{F850LP}$ ) (Giavalisco et al. 2004), *VLT/ISAAC*, ( $J$ ,  $K_s$ ) (Retzlaff et al. 2010), *Spitzer/IRAC* ( $3.6\mu m$ ,  $4.5\mu m$ )<sup>2</sup>, as well as spectroscopic data taken with the *VLT/FORS2* 300I grism by the ESO-GOODS survey<sup>3</sup> (Vanzella et al. 2005, 2006, 2008; Balestra et al. 2010) and the K20 survey (Cimatti et al. 2002).

## 2.3. Cataloging of observations and samples selection

The resulting datasets for the three clusters and the field have homogeneous depths and wavelength coverage, allowing the application of similar selection criteria for both samples. This is a crucial point for stellar population studies, so that we do not have different levels of systematic biases in the analyses.

The data allow the reconstruction of galaxy spectral energy distributions (SEDs) by entirely sampling the relevant spectrum range emitted by all the different stellar populations. For each observing band we produce catalogs from matched aperture photometry, with an aperture of radius 1.5'' and an aperture correction out to 7'' radius, as described in Rettura et al. (2006); Raichoor et al. (2011).

---

<sup>2</sup>CDFS imaging is publicly available through the GOODS collaboration web-site: <http://www.stsci.edu/science/goods/>.

<sup>3</sup>Spectroscopic data are publicly available through the web-site: <http://www.eso.org/sci/activities/projects/goods/MasterSpectroscopy.htm>.

The availability of 8 to 10 passbands spanning such a large wavelength range enables the estimate of accurate stellar masses (Rettura et al. 2006), ages and star formation histories of ETGs (Rettura et al. 2010) and enables us to directly compare galaxy properties of homogeneously selected samples of ETGs in both environments.

Specifically, we measure stellar population parameters of Lynx E and Lynx W early-type cluster galaxies and compare them with those found for similarly-selected samples of cluster and field contemporaries drawn from CL1252 at  $z = 1.237$  and CDFS at  $z = 1.237 \pm 0.15$ .

We estimated stellar masses from both  $K_s$  band observations and SED fitting. The two estimates give similar mass limits. The depth of the *VLT*/ISAAC and *KPNO*/FLAMINGOS  $K_s$ -band images and the extended multi-wavelength data for all fields allows us, in fact, to define complete mass-selected samples. The reader is referred to Gobat et al. (2008); Raichoor et al. (2011) for more details. Here, we note that overall photometric completeness is obtained if we limit our analysis to stellar masses larger than  $M_{lim} = 5 \cdot 10^{10} M_{\odot}$ <sup>4</sup>.

A selection of Lynx E, Lynx W and CL1252 passive ETGs along the cluster red sequence is efficiently provided by a color selection of  $i_{F775W} - z_{F850LP} > 0.8$  (Blakeslee et al. 2003; Mei et al. 2006a,b, 2009, 2011).

For CL1252, in the spectroscopic sample of Demarco et al. (2007), there are 22 red-sequence galaxies ( $i_{F775W} - z_{F850LP} > 0.8$ ) with  $M_* > M_{lim}$ , of which 18 are classified as passive ETGs, i.e. without detectable [OII] or other emission lines in their observed spectra. For Lynx E and Lynx W, in the combined photometric and spectroscopic samples (Mei et al. 2006a; Stanford et al. 1997; Rosati et al. 1999; Stanford et al. 2001; van Dokkum & Stanford 2003; Holden et al. 2011) there are 21 red-sequence galaxies with  $M_* > M_{lim}$ , of which 17 are classified as passive ETGs. Specifically, there are 10 passive spectroscopically-confirmed ETGs in Lynx E, and 3 in Lynx W. We remark that, to improve the statistics, we have also included into the Lynx ETGs sample, 3 photometrically-confirmed members of Lynx E and 1 photometrically-confirmed member of Lynx W both with  $i_{F775W} - z_{F850LP} > 0.8$  and  $M_* > M_{lim}$ , thus resulting in a total sample of 17 Lynx E+W ETGs. It is important to note that the removal from our sample of these 4 galaxies, whose cluster-membership was assessed on the basis of a (8-9 band) photometric-redshift only, would not change the main conclusions of this study.

For the corresponding CDFS sample of field contemporaries, the same criteria yield 27 passive ETGs in CDFS with FORS2 spectra giving redshift in the range  $z = 1.237 \pm 0.15$  (for more

---

<sup>4</sup>Assuming Salpeter Initial Mass Function (IMF), with lower and upper cutoffs,  $m_L = 0.1 M_{\odot}$  and  $m_U = 100 M_{\odot}$ , respectively. We refer the reader to Rettura et al. (2006); Raichoor et al. (2011) for a discussion on the dependence of inferred stellar population properties on the actual choice of the IMF.

details see also Gobat et al. (2008); Rettura et al. (2010)).

We also remark that, adopting the classification scheme of Postman et al. (2005), visual morphological analysis of the HST/ACS images available for all samples indicates that all our red, passive ETGs also show typical elliptical or lenticular morphology.

As reported in Rettura et al. 2010, we also remind that the spectroscopic follow-up for CL1252 is more complete at the low-mass end than in CDFS. Thus, our sample of ETGs in CDFS is likely to be more incomplete at the low-mass end than the CL1252 and Lynx ones. We will return to this point when discussing our results in Section 4.

### 3. Data Analysis: derivation of stellar population properties

The data described in the previous section are used to infer fundamental physical properties of similarly mass-selected samples of early-type galaxies (13 ETGs in the Lynx E, 4 in Lynx W, 18 in CL1252 and 27 in the CDFS). Adopting a similar approach to Rettura et al. (2006, 2010), we derive stellar masses, star formation histories and ages for each ETG in Lynx E and Lynx W using multi-wavelength PSF-matched aperture photometry from 8 passbands, from observed  $u'$ -band to observed  $4.5\mu m$ . For each galaxy, we compare the observed SED with a set of composite stellar populations (hereafter, CSP) templates computed with the Bruzual & Charlot (2003) models, assuming solar metallicity, Salpeter (1955) Initial Mass Function (hereafter, IMF) and no dust.

Similarly to Rettura et al. (2006) we checked the effect of dust extinction on the best-fit stellar masses by including a fourth free parameter,  $0.0 < E(B - V) < 0.4$ , following the Cardelli et al. (1989) prescription. Performing the SED fit on 13 Lynx E+W ETGs (all with complete  $u'$ -to- $4.5\mu m$  coverage) and on 22 CDFS ETGs (all with complete  $U$ -to- $4.5\mu m$  coverage), we find that in  $\sim 50\%$  of the cases  $E(B - V) \leq 0.05$  gives the best fit. In the remaining cases values of  $E(B - V) \leq 0.2$  are found and no particular trend with mass nor environment is found either, hence supporting the validity of the dust-free assumption we make throughout this work.

For our CSP models, we assume the following grid of exponentially-declining star formation history (SFH) scenarios,  $\Psi(t, \tau)$ :

$$\Psi(t, \tau) = SFR_0 \cdot e^{-t/\tau} \left[ \frac{M_\odot}{yr} \right], \quad (1)$$

where  $0.05 \leq \tau \leq 5$  Gyr,  $SFR_0$  is the initial SFR at the onset of star formation, and

$t$  is the time since the onset of star formation<sup>5</sup> of the stellar population model formed at a lookback time  $T(\bar{z}) + t$ , with, e.g.,  $T \simeq 8.67$  Gyr at the epoch of observation ( $\bar{z} \simeq 1.3$ ).

In determining galaxy model ages, masses and star formation histories from SED fitting, is important to understand how much our estimates could possibly be affected by “age-metallicity”<sup>6</sup> and “age-SFH” degeneracies. We note that in Rettura et al. (2010) we have demonstrated that the use of photometric information coming from the rest-frame UV is crucial to distinguish the different parameters of the stellar population modeling, allowing us to break the “age-SFH degeneracy”. It is also important to note that the rest-frame UV remains also largely unaffected by the “age-metallicity” degeneracy, which plagues optical studies (Worthey 1994).

Furthermore, the reliability, at  $z > 1$ , of stellar population parameters inferred in the rest-frame NIR regime ( $\lambda_{obs} \sim 2\mu m$ ) has long been debated (Maraston 1998) because of the different implementation of the relevant short-duration thermally pulsating (TP) AGB phase in the different stellar population synthesis models. However, in Rettura et al. (2006) we have shown that different stellar population models actually yield overall consistent stellar masses, within the typical errors, for ETGs at  $z \sim 1.0$ . It is clear that the inferred SFH (and age) is model-dependent and is generally not a unique solution, however the relative difference in the underlying stellar population is still significant. In fact, in Rettura et al. (2010) we have shown that when comparing *cluster vs. field*  $\tau$ s and ages, the *relative* differences among samples (or lack thereof, as in their Fig. 8) were similar regardless of the actual stellar population code used, not affecting their conclusions.

Hence, since our study is indeed aimed at constraining the relative difference of galaxy stellar population parameters in a *Cluster vs. Cluster* and *Cluster vs. Field* fashion, we will only show here the results obtained with the Bruzual & Charlot (2003) models, in order to facilitate direct comparison with previous studies in the literature. Note that in Raichoor et al. (2011) we also present an extensive discussion on systematics due to choice of the stellar population models at  $z \sim 1.3$ .

To account for the average age of the bulk of the stars in a galaxy, we refer throughout this paper to *star-formation weighted* ages,  $\langle t \rangle_{SFH}$ , defined as:

$$\langle t \rangle_{SFH} \equiv \frac{\int_0^t (t - t') \Psi(t', \tau) dt'}{\int_0^t \Psi(t', \tau) dt'}. \quad (2)$$

---

<sup>5</sup>The range of acceptable  $t$ s for a given galaxy has been limited by the age of the universe at its observed redshift.

<sup>6</sup>We employ the working assumption that the most-massive ETGs have all solar metallicities.

Assuming  $\Psi(t', \tau)$  as in Eq. 1 we obtain,

$$\langle t \rangle_{SFH} = \frac{t - \tau + \tau \cdot e^{-\frac{t}{\tau}}}{1 - e^{-\frac{t}{\tau}}}, \quad (3)$$

where  $t$  is the time elapsed since the onset of star formation (SF).

By comparing each observed SED with these atlases of synthetic spectra, we construct a 3D  $\chi^2$  space spanning a wide range of star formation histories, model ages and stellar masses. The galaxy mass in stars  $M_*$ , the inferred  $\langle t \rangle_{SFH}$  and the  $\tau$  of the models giving the lowest  $\chi^2$  are taken as the best-fit estimates of the galaxy stellar mass, age, and SFH timescale throughout this work. We note that this procedure results in typical errors for galaxy ages of  $\sim 0.5$  Gyr, and for  $\tau$  of  $\sim 0.2$  Gyr (Rettura et al. 2010). Typical uncertainties on the mass determination are about  $\sim 40\%$  (i.e., 0.15 dex) (Rettura et al. 2006).

#### 4. Results and Discussion

In the top panel of Fig. 1 we plot the inferred stellar masses as a function of the  $U - B$  rest-frame color for the mass-selected samples of CL1252, Lynx E and Lynx W ETGs, resulting in a very similar distribution. In the bottom panel of Fig. 1 we show the rest-frame  $U - B$  color - mass diagram of the combined samples of cluster (red circles) and field (blue circles) ETGs. To have a very simple estimate of the scatter of the color-mass relation, as derived from the SED fitting, we derive the scatter around the fit using a Tukey’s biweight (Press et al. 1992). We simply calculated the uncertainty in the scatter estimation by bootstrapping on 1,000 simulations. For the Lynx cluster sample, CL1252, and field galaxies, we obtain a scatter of  $0.031 \pm 0.010$ ,  $0.042 \pm 0.010$ , and  $0.050 \pm 0.008$ , respectively. These are intrinsic scatters as predicted from the best SED fitting, and do not take into account uncertainties in the fitting methods. Field ETGs galaxies are distributed around the cluster red-sequence, although they seem to show a larger scatter, especially at lower masses. We will need more statistics and better estimates of uncertainties to draw a stringent conclusion, since the cluster and field overall scatters could still be consistent within the uncertainties.

As we apply the method described in section §3, we are able to directly compare the relative distribution of galaxy stellar population properties for the different samples. Stellar masses ranges from  $M_{lim}$  to  $4 \cdot 10^{11} M_\odot$  except for three CL1252 bright galaxies and one galaxy in the field (bottom panel of Fig. 1). We do not find any of the Lynx clusters ETGs to be more massive than  $3 \cdot 10^{11} M_\odot$  (top panel of Fig. 1).

We want to tests the hypothesis that two samples stellar-mass distributions have the

same median against the hypothesis that they differ at the 5% significance level. The Mann-Whitney U-Test suggests that the distributions are likely to be similar (median probability of 44%). We also study the Kolmogorov-Smirnov statistic and associated probability that the two arrays of data are drawn from the same distribution, yielding a similar result. A high value (67%) of probability shows that the cumulative distribution function of the cluster stellar masses is not significantly different from the field one.

As shown in Fig. 2, we also find that all clusters show the same relative distributions of lookback time since the onset of star formation ( $T(\bar{z}) + t$ , top panel) and stellar mass assembly timescales, ( $\tau$ ; bottom panel). In fact both the Mann-Whitney U-Test (median probability of 10%, 21 %) and the K-S statistics (75%, 91% of probability) also elucidate that the distributions are very similar.

This lack of cluster-to-cluster variation may well indicate that these three clusters experienced similar evolutionary processes, resulting in similar stellar population properties shown by their member ETGs. Since these samples of cluster ETGs are found to be very similar from a stellar population point-of-view, we can combine them into one sample of 35 ETGs, representative of the Cluster environment at  $z \sim 1.3$ , apt for comparison with the sample of 27 CDFS ETGs, representative of the Field environment.

Thus we compare the distribution of the star-formation weighted ages ( $\langle t \rangle_{SFH}$ , top panel of Fig. 3) as a function of stellar mass in both environments. We find the distributions to be overall very similar, as also shown by the histograms of lookback times since the onset of star formation (top panel of Fig 4) and by the histograms of the lookback times to  $\langle t \rangle_{SFH}$  (bottom panel of Fig 4). Note that Mann-Whitney U-Test returns a median probability of 18% and the K-S statistics a 60% of probability that the last two data values are drawn from the same distribution. These results imply that no significant delay in relative age is found for ETGs in either environments. Using BC03 models, we find that  $\sim 80\%$  of ETGs have SF-weighted ages in the range  $3.5 \pm 1.0$  Gyr in both cluster and field, in qualitative agreement with previous CMR studies (Blakeslee et al. 2003; Mei et al. 2006a,b).

In the bottom panel of Fig. 3 we show, for both samples, the dependence of star-formation weighted ages,  $\langle t \rangle_{SFH}$ , on stellar mass. It is evident that the ages of ETGs only depends on their mass, i.e. the halo mass in which they reside, which is in agreement with the so-called *downsizing* scenario of galaxy formation (Cowie et al. 1996). We note that this scenario have also been reconciled, with the introduction of various forms of so-called feedback mechanisms, with the recent versions of semi-analytic models based on  $\Lambda$ CDM cosmogony (De Lucia et al. 2006; Bower et al. 2006; Menci et al. 2008).

To summarize, we find that cluster galaxy (star formation weighted) ages have the same

relative distribution as their field contemporaries: no significant delay in their formation epochs is found within the errors ( $\sim 0.5$  Gyr). We remind that this result is in remarkably good agreement with the ones derived by van Dokkum & van der Marel (2007) and di Serego Alighieri et al. (2006) from the evolution of the  $M/L$  ratio. However our method is able to extend this kind of analysis to less massive system than the typical targets of FP studies at  $z \sim 1$ .

Despite of the fact that cluster and field galaxy formation epochs are found to be similar, it could still be possible that the timescales of their SFH are significantly different. As mentioned above, the data have shown that the distributions of cluster and field optical colors were slightly different. As a function of the stellar mass, cluster galaxies are found to lie on a very tight red-sequence, while those in the field populate the same color-sequence with a slightly larger scatter (Fig. 1).

This piece of evidence finds a natural explanation in the framework of our modeling. As shown in the top-left panel of Fig. 5, as a function of stellar mass, we find that field ETGs show longer SFH timescales than their cluster contemporaries, which tend to assemble their mass with the shortest  $\tau$  at any given mass. In fact the Mann-Whitney U-Test confirms that the distributions are very likely to be different (median probability of 0.07%). The Kolmogorov-Smirnov statistic also yields an associated probability that the two distribution of  $\tau$ s are drawn from the same distribution of just 0.8%.

If galaxies continue to form stars following the exponential decay of Eq. 1, we can derive the time,  $t_{0.8}$  needed to form 80% of the stars they would have at  $z = 0$ . As shown by top-right panel of Fig. 5 and bottom panel of Fig. 6), we find that  $\sim 1$  Gyr after the onset of star formation 75% of cluster ETGs have already assembled most of their of their final mass. By the same time, less than 35% of field ETGs have.

The bottom-left panel of Fig. 5 shows the relative distributions of inferred initial star formation rate,  $SFR_0$ , as a function of stellar mass. More than 30% of cluster galaxies have higher  $SFR_0$  and smaller  $\tau$ s than any other field contemporaries, indicating they have experienced a much more intense star formation at early times than field galaxies. As a result, at the time of observation, cluster ETG specific star-formation rates, defined as the SFR divided by the galaxy stellar mass,  $SSFR$ , are lower than those of the field ones (bottom-right panel of Fig. 5). Indeed the Mann-Whitney U-Test confirms that the distributions of  $SSFR$  are likely to be different (median probability of 1.3%). The Kolmogorov-Smirnov statistic yields an associated probability of 0.5% that the two distribution of  $\tau$ s are drawn from the same parent distribution.

As summarized by the histograms in Fig. 6, the distributions of  $\tau$  and  $t_{0.8}$  in clusters

and in the field are found to be very different. These results clearly indicate a dependence of ETGs star formation histories on the environment, in agreement with previous studies based on a comparison of a single cluster to the field (Gobat et al. 2008; Rettura et al. 2010; Menci et al. 2008).

As discussed in Rettura et al. (2010), we recall that our field sample is more deficient in lower mass objects than the cluster sample because of a less extensive follow-up of spectroscopic targets in the field as compared to that in the cluster.

However, even if the field sample were corrected for completeness, this would likely result in a larger fraction of field ETGs at low mass, which are the ones that we find with longer  $\tau$ s and  $t_{0.8s}$ , higher  $SSFR$ s and lower  $SFR_{0s}$ . Hence a correction would actually amplify the difference between the typical mass assembly timescales of the two samples, and so not affect our conclusions.

## 5. Conclusions

We have studied the environmental dependence of early-type galaxy stellar population properties at  $z \sim 1.3$  based on high-quality, multi-wavelength photometry available in 8-10 passbands from  $U$  to  $[4.5\mu m]$ : sampling the entire relevant domain of emission of the different stellar populations, from rest-frame far-ultraviolet to the infrared.

We have similarly analyzed mass-selected samples of ETGs belonging to the cores of three massive clusters (RXJ0849+4452 at  $z=1.261$ , RXJ0848+4453 at  $z=1.273$ , RDCS1252.9-2927 at  $z=1.237$ ) and compared their stellar population properties with those measured in a similarly selected sample of field contemporaries drawn from the GOODS-S survey.

We have derived stellar masses, (star formation weighted) ages, and star formation histories, parameterized as timescales,  $\tau$ , from exponentially declining CSP model templates built with BC03 models for samples of massive ( $M > 5 \cdot 10^{10} M_{\odot}$ ), passive (no-emission line in their spectra) ETGs at  $z \simeq 1.3$ . Apart from a lower level of spectroscopic completeness for the least massive field galaxies, that we find not to affect our conclusions, our sample has the advantage of being photometrically complete at our mass limit and having galaxy types (passive or star-forming members) assigned spectroscopically.

This work extends the analyses performed on a single-cluster by Rettura et al. (2010); Gobat et al. (2008) to two more clusters at  $z \sim 1.3$ : doubling the size of the cluster ETG sample.

Hence, on the basis of the new data we are able to affirm that:

- we find no significant difference in the derived stellar population properties of  $z \sim 1.3$  ETGs belonging to different X-ray luminous clusters (RXJ0849+4452 & RXJ0848+4453, RDCS1252.9-2927).

Moreover the comparative statistical analysis performed in this work on the extended dataset corroborates the results obtained in our previous study (Rettura et al. 2010), that we summarize as follows:

- Field ETGs galaxies are distributed around the cluster ETG red-sequence, although they seem to show a larger scatter, especially at lower masses. We will need more statistics and better estimates of uncertainties to draw a more stringent conclusions, since the cluster and field overall scatters could still be consistent within the uncertainties. However, we remind that the small scatter in cluster environments remains a challenge for semi-analytical galaxy evolution models (Menci et al. 2008).
- We find no significant delay in the star formation weighted ages of massive ETGs observed in all clusters and in the field at  $z \simeq 1.3$ .  
The age of ETGs increase with galaxy mass in all environments, which is in agreement with the *downsizing* scenario. The site of active star formation must have shifted from the most massive to the less massive galaxies as a function of the cosmic time. The formation epochs of ETGs only depends on their mass and not on the environment they live in. This result is in remarkably good agreement with those obtained from the evolution of the  $M/L$  ratio (e.g. van Dokkum & van der Marel (2007); di Serego Alighieri et al. (2006)).
- However, the data show that cluster and field SFHs are significantly different. Field ETGs best-fit models span a different range of timescales than their cluster contemporaries, which are formed with the shortest  $\tau$  at any given mass. This result is quantitatively consistent with the predictions of current galaxy formation models based on the latest rendition of semi-analytic models (Menci et al. 2008).
- We find that 1 Gyrs after the onset of star formation 75% of cluster ETGs have already assembled 80% (or more) of their final mass, while, by the same time, less than 35% of field ETGs have.
- Accordingly, cluster ETGs specific star-formation rates at the time of observation are found to be smaller than those of the field ones, implying that the last episode of star formation must have happened more recently in the field than in the cluster.

While cluster and field galaxy observed at  $z \simeq 1.3$  form at a similar epoch in a statistical sense, a high density environment appear to be able to trigger a much more rapid and homogenous mass assembly event for the ETGs, limiting the range of possible star-formation processes. In fact, more than 30% of cluster galaxies are found with higher initial  $SFR_0$  and smaller  $\tau_s$  than any other field contemporaries, indicating they have experienced much more intense star formation at early times than field galaxies. In low density environments, this effect must rapidly fade as ETGs display a much broader range of possible star formation histories.

A.R. is grateful to Gabriella de Lucia, Raphael Gobat, Roderik Overzier, Maurilio Pannella, Veronica Strazzullo and Loredana Vetere for useful discussions.

Fig. 1.— *Top panel:* Rest-frame  $U - B$  color-mass diagram of mass-selected samples of CL1252 (green circles), Lynx E (red circles) and Lynx W (orange circles) passive cluster ETGs. Uncertainties in the stellar mass are  $\sim 0.15$  dex. *Bottom panel:*  $U - B$  color - mass diagram of the combined samples of Cluster (red circles) and Field (blue circles) ETGs. Field ETGs galaxies are distributed around the cluster red-sequence, although are found with a larger scatter.

Fig. 2.— *Top Panel:* Histograms of the lookback times to the onsets of star formation for the cluster samples. Uncertainties in ages are  $\sim 0.5$  Gyr. No cluster-to-cluster variation of the galaxy ages is found. *Bottom Panel:* Formation *timescales*,  $\tau$ , histograms for the different cluster samples. No cluster-to-cluster variation of the galaxy formation timescales is found. Uncertainties in stellar masses and  $\tau$  are  $\sim 0.15$  dex and  $\sim 0.2$  Gyr, respectively.

Fig. 3.— *Top Panel:* The dependence of the star formation weighted ages on the galaxy mass and environment. No dependence of ages on the environment is found. *Bottom Panel:* The dependence of the lookback time to star formation weighted ages on the galaxy mass, and environment. Uncertainties in stellar masses and ages are  $\sim 0.15$  dex and  $\sim 0.5$  Gyr.

Fig. 4.— Histograms of the field (solid blue line) and cluster (solid red line) lookback times since the onset of star formation (top panel) and of the star formation weighted ages (bottom panel). No dependence of the ETG ages with the environment. Uncertainties in age determination are  $\sim 0.5$  Gyr.

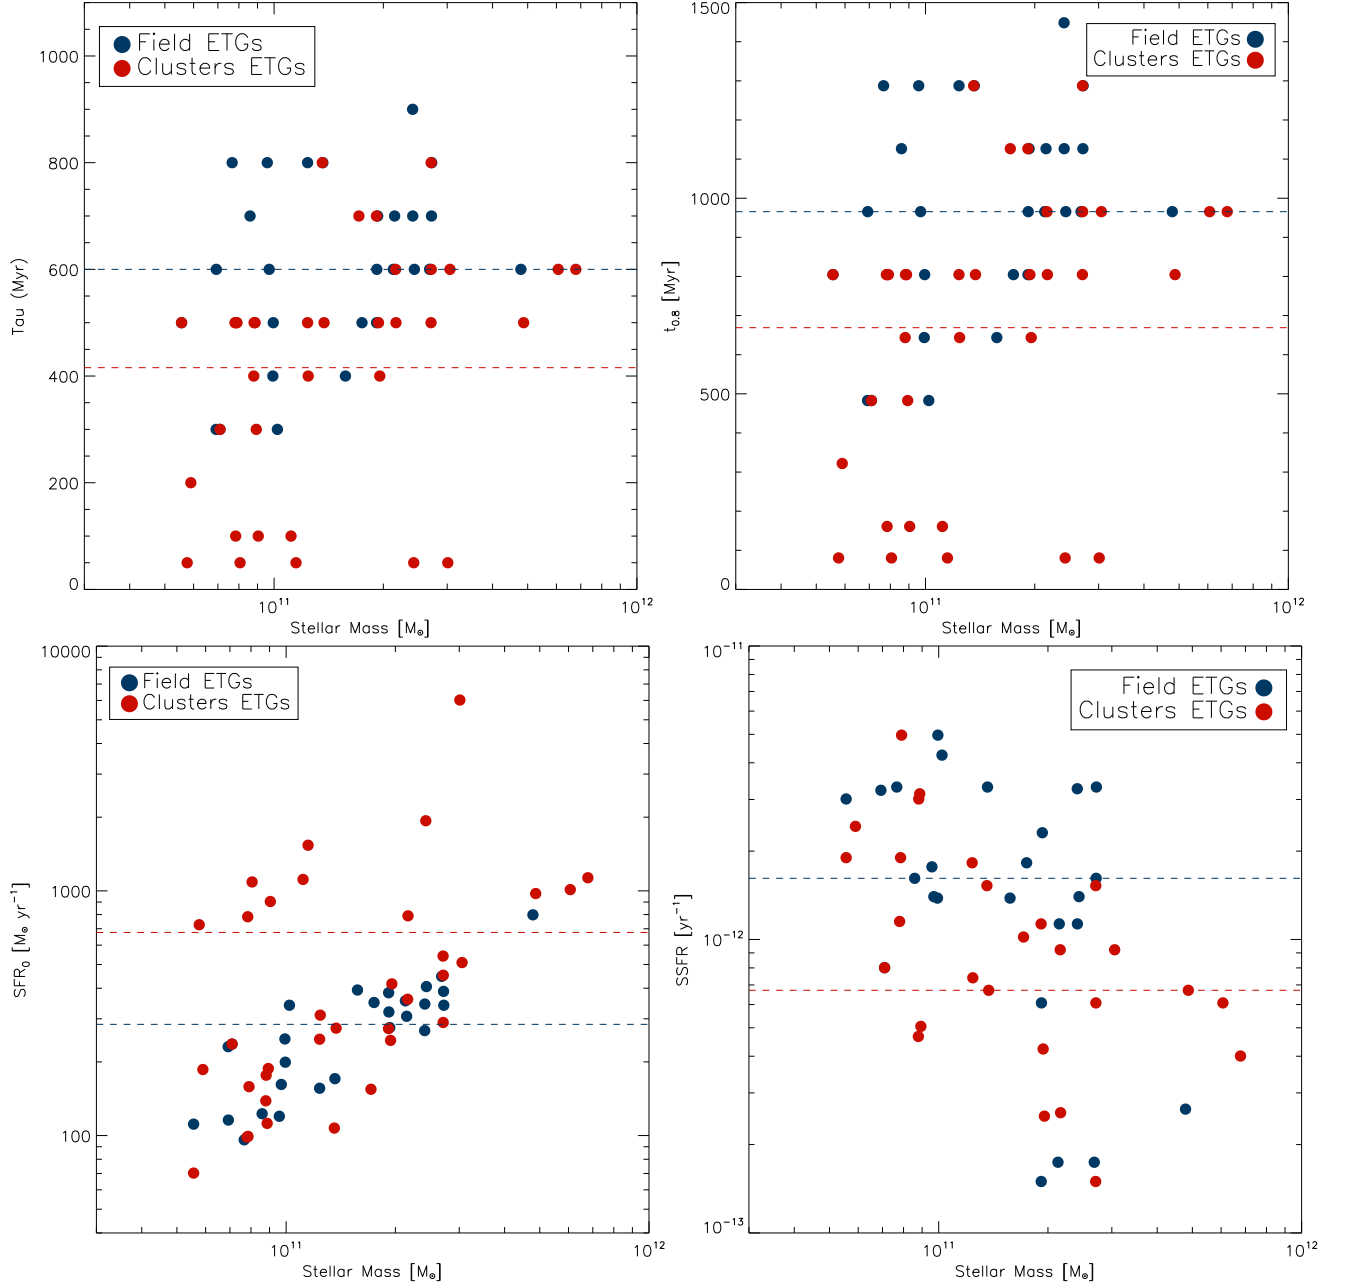

Fig. 5.— *Top-left Panel:* Formation *timescales*,  $\tau$ , of ETG as a function of their stellar mass and environment. *Top-right Panel:* As a function of stellar mass and environment, the diagram of the time,  $t_{0.8}$ , needed for a given galaxy to form 80% of the stars it will have at  $z = 0$ . *Bottom-left Panel:* Dependence of the initial star formation rate,  $SFR_0$ , of ETGs as a function of their stellar mass and environment. *Bottom-right Panel:* Specific SFRs,  $SSFR$ , of ETGs as a function of their stellar mass and environment. The mean error in stellar age is 0.5 Gyr. Uncertainties in stellar masses,  $\tau$  and  $t_{0.8}$ , are  $\sim 0.15$  dex,  $\sim 0.2$  and  $\sim 0.4$  Gyr, respectively. In all panels, as a function of stellar mass, the median values of the different cluster (red dashed line) and field (blue dashed line) stellar population parameter distributions are also indicated.

Fig. 6.— *Top Panel:* Histogram of the formation *timescales*,  $\tau$ , of ETGs in both environments. *Bottom Panel:* Histogram of the times,  $t_{0.8}$ , needed for a given galaxy to form 80% of the stars it would have at  $z = 0$ , for both environments. Uncertainties in the determination of  $\tau$  and  $t_{0.8}$  are  $\sim 0.2$  and  $\sim 0.4$  Gyr, respectively.
